Generalized Tonic-clonic Seizures Following Spinal Anesthesia Using Bupivacaine for Cesarean Section: A Case Report

Jasleen Kaur1, Sukhman K Gill2, Anita Kumari3, Chiteshwar Walia4, Harmandeep Kaur5

ABSTRACT

Background: Generalized seizures have been reported following epidural anesthesia but rarely after spinal anesthesia.

Aim and objective: The aim and objective of our study is to create awareness about a rare possibility of bupivacaine-induced generalized tonic-clonic seizures.

Case description: A 19-year-old primigravida with no history of any medical disease had episodes of generalized tonic-clonic seizures following spinal anesthesia. The patient lost consciousness and was immediately intubated after two episodes of seizures. Later on, she was shifted to the intensive care unit for mechanical ventilation.

Conclusion: Although convulsions following spinal anesthesia are rare, parturients can develop complications such as generalized tonic-clonic seizures, respiratory depression, and loss of consciousness following spinal anesthesia. These patients require stringent and meticulous monitoring in perioperative period as those for general anesthesia.

Keywords: Bupivacaine, Cesarean section, Spinal anesthesia, Tonic-clonic seizures.

INTRODUCTION

Spinal anesthesia for cesarean section has many advantages over general anesthesia such as it avoids airway manipulation, lessens the risk of gastric aspiration, avoids use of anesthetic agents, have less neonatal depression, and maintains airway reflexes and consciousness.1 There are several complications related to spinal anesthesia in cesarean section such as postdural puncture headache (PDPH), back pain, abscess, hematoma, paresthesia, motor weakness, and rarely myoclonus.2,3 But generalized tonic-clonic seizures (GTCS) are rarely reported. Bupivacaine is the most commonly used local anesthetic in spinal anesthesia during cesarean section, and it has more central nervous system and cardiovascular system side effects than newly discovered local anesthetics such as levobupivacaine and ropivacaine.4 Here, we report a rare case of primi parturient who developed GTCS following spinal anesthesia using bupivacaine.

CASE DESCRIPTION

A 19-year-old primigravida with period of gestation of 39 + 5 weeks was suggested for emergency cesarean section with indication of meconium-stained liquor. Preoperative investigations and electrocardiography were within normal limits, with hemoglobin 12.4 g%, TLC count of 10,400, and PTI 93.3%. Her trimester history was uneventful. She was premedicated with inj. ranitidine and inj. metoclopramide. On arrival to the operating room, monitors were attached. She had stable vitals with heart rate (HR) of 92 beats per minute (bpm), blood pressure (BP) was 124/76 mm Hg in left arm supine, and saturation (SpO2) was 99% on room air. Intravenous (I/V) line was secured, and the patient was preloaded with 500 mL of ringer lactate. Under all aseptic precautions, spinal anesthesia (I/V) line was secured, and the patient was preloaded with 500 mL of ringer lactate. Under all aseptic precautions, spinal anesthesia was given in left lateral decubitus position using 25-Gauge Quincke’ needle in L3 to L4 intervertebral space using midline approach; 2.2 mL of 0.5% heavy bupivacaine was administered after checking free flow of cerebrospinal fluid (CSF). Patient was made supine immediately, and vitals were checked. After checking adequate effect, surgery was allowed to commence. A healthy female baby was delivered. On table at the time of closure, patient started complaining of headache and neck rigidity. She had an episode of GTCS and became unconscious after two such episodes. At the time of GTCS, her HR was 102 bpm, BP was 134/74 mm Hg, and SpO2 was 95% on oxygen mask. An oral airway was kept in situ, and the patient was immediately taken on bag and mask ventilation with 100% oxygen. Propofol 70 mg was given to facilitate intubation. After intubation she was shifted to intensive care unit (ICU) for mechanical ventilation and further management.

The patient had two more episodes of GTCS in next 6 hours on ventilator and was kept sedated with an infusion of midazolam and butorphanol. A provisional diagnosis of either bacterial or viral or aseptic meningitis was made, so I/V prophylactic antibiotics were administered. Levetiracetam 500 mg I/V 12 hourly and...
sodium valproate in a dose of 10 mg/kg/day I/V were added to control seizures. Magnetic resonance imaging was done which revealed bulky and edematous sulcogyrual folds with abnormal areas of signal intensity along the leptomeninges—likely to be leptomeningitis with associated evolving cerebritis (possibility of chemical meningitis) (Fig. 1). CSF tap examination was done and was within normal limits with 12 (nine neutrophils and three lymphocytes), protein 103, glucose 76, and ADA 16. Routine blood investigations, electrolytes, and blood gas analysis were also normal throughout her stay in the ICU. Based on investigations and clinical condition, diagnosis of aseptic meningitis was made, and she was kept on supportive treatment along with empirical antibiotics and antiepileptics. After 2 days, sedation was tapered off and the patient became conscious. Ventilatory support was weaned off according to her clinical condition and was then extubated. Patient was shifted to general ward after an uneventful recovery and got discharged on the fifth postoperative day. At 3 months follow-up, the patient had no complaint of any neurological deficit or any similar episodes of seizures.

**Discussion**

Several neurological complications associated with spinal anesthesia are reported in the literature such as meningitis, arachnoiditis, neurological injury, PDPH, paresthesias, and myoclonus, but, GTCS is rarely reported.3–7

Kim et al. in 2011 reported a similar case report of a parturient posted for cesarean section which was being conducted under spinal anesthesia, who had GTCS 3 minutes after the delivery of baby. She was intubated under the cover of propofol and succinylcholine and oxygenated on manual bag and mask ventilation. After 30 minutes, spontaneous respiration returned. After checking for responsiveness and vitals, on-table extubation was done. Her postoperative period was uneventful. So they concluded that intrathecal bupivacaine may lead to status epilepticus.8

**Conclusion**

Convulsions following spinal anesthesia are rare. Parturients can develop complications such as GTCS, respiratory depression, and loss of consciousness following spinal anesthesia. So these patients require stringent and meticulous monitoring in the perioperative period. Treatment of seizures involves managing convulsions, rectifying the respiratory depression, and metabolic acidosis in such cases is of utmost importance.
